ABSTRACT

Rett syndrome (RTT) is a rare congenital disorder which in most cases (95%) is caused by methyl-CpG binding protein 2 (MECP2) mutations. RTT is characterized by regression in global development, epilepsy, autistic features, acquired microcephaly, habitual hand clapping, loss of purposeful hand skills, and autonomic dysfunctions. Although the literature has demonstrated decreased volumes of the cerebrum, cerebellum, and the caudate nucleus in RTT patients, surface-based brain morphology including cortical thickness and cortical gyriﬁcation analyses are lacking in RTT. We present quantitative surface- and voxel-based morphological measurements in young children with RTT and Rett-like syndrome (RTT-l) with MECP2 mutations. The 8 structural T1-weighted MR images were obtained from 7 female patients with MECP2 mutations (3 classic RTT, 2 variant RTT, and 2 RTT-l) (mean age 5.2 [standard deviation 3.3] years old). Our analyses demonstrated decreased total volumes of the cerebellum in RTT/RTT-l compared to gender- and age-matched controls (t (22) = -2.93, p = .008, Cohen's d = 1.27). In contrast, global cerebral cortical surface areas, global/regional cortical thicknesses, the degree of global gyriﬁcation, and global/regional gray and white matter volumes were not statistically signiﬁcantly different between the two groups. Our findings, as well as literature ﬁndings, suggest that early brain abnormalities associated with RTT/RTT-l (with MECP2 mutations) can be detected as regionally decreased cerebellar volumes. Decreased cerebellar volume may be helpful for understanding the etiology of RTT/RTT-l.

1. Introduction

Rett syndrome (RTT) (OMIM 312750) is a rare congenital disorder characterized by autistic features, acquired microcephaly, habitual hand clapping, loss of purposeful hand skill, and autonomic dysfunction (Neul et al., 2010; Singh and Santosh, 2018). Mutations of methyl-CpG binding protein 2 (MECP2) on the X chromosome are identiﬁed in over 90% of patients with a typical RTT phenotype. MECP2 mutations were mainly identiﬁed in females with RTT and Rett-like syndrome (RTT-l), while males with MECP2 mutations mainly present with severe encephalopathy and fulﬁll the criteria of variant RTT as they develop (Neul et al., 2018; Soffer and Sidlow, 2016; Tokaji et al., 2018).

Typical RTT patients show normal development during infantile periods, followed by a severe decline in global development, decreased head circumference, and the emergence of epilepsy after 6–18 months (Neul et al., 2010; Krishnaraj et al., 2017; Hagberg et al., 2001; Dolce et al., 2013). This regression in RTT has motivated many research studies towards developing clinical interventions for RTT (as reviewed (Singh and Santosh, 2018)) and searching for biomarkers for early di‐agnosis of RTT using multiple techniques including neuroimaging.

Few studies have focused on quantitative brain morphology of RTT which has included 4 classical studies with manual trace-based measurements (Reiss et al., 1993; Casanova et al., 1991; Murakami et al., 1992; Subramaniam et al., 1997) as well as 1 study with voxel-based measurements (Carter et al., 2008). Although these studies showed decreased volumes of the cerebrum, cerebellum, and the caudate nucleus (Reiss et al., 1993; Carter et al., 2008), surface-based brain morphology including cortical gyriﬁcation and regional cortical thickness has not been explored. In this study, we report results from a quantitative brain morphological study with surface- and voxel-based

measurements in young children with RTT/RTT-l.

2. Patients and methods

2.1. Patients

The Institutional Review Board at Boston Children Hospital (BCH) approved this retrospective study. We assembled our listing of RTT susceptible patients using i2b2 (http://web2.tch.harvard.edu/i2b2). The Institutional Review Board at Boston Children Hospital (BCH) approved this retrospective study. We assembled our listing of RTT susceptible patients using i2b2 (http://web2.tch.harvard.edu/i2b2). Based on clinical records at BCH, clinical diagnosis by a pediatric neurolologist was confirmed using revised RTT diagnostic criteria (Neul et al., 2010). As shown in Tables 1 and 3 patients fulfilled the classic RTT criteria, and 2 patients fulfilled the variant RTT criteria. The other 2 patients were RTT-l; although 2 main criteria were fulfilled, only 4 supportive criteria were fulfilled (one more supportive criterion is necessary to critically diagnose as RTT). We obtained 8 MRI data sets and electronic medical records from those 7 cases of RTT/RTT-l. We obtained 8 MRI data sets and electronic medical records from those 7 cases of RTT/RTT-l. The 16 gender- and age-matched normal controls (NC) were selected from our in-house database composed of electronic medical records from healthy participants without neurological disorders, neuropsychological disorders or epilepsy (Levman et al., 2017). Both datasets (RTT/RTT-l and NC) were comprised of examination acquired at BCH on the same suite of MRI scanners. We assembled our listing of RTT susceptible patients using i2b2 (http://web2.tch.harvard.edu/i2b2). Based on clinical records at BCH, clinical diagnosis by a pediatric neurolologist was confirmed using revised RTT diagnostic criteria (Neul et al., 2010). As shown in Tables 1 and 3 patients fulfilled the classic RTT criteria, and 2 patients fulfilled the variant RTT criteria. The other 2 patients were RTT-l; although 2 main criteria were fulfilled, only 4 supportive criteria were fulfilled (one more supportive criterion is necessary to critically diagnose as RTT). We obtained 8 MRI data sets and electronic medical records from those 7 cases of RTT/RTT-l. We obtained 8 MRI data sets and electronic medical records from those 7 cases of RTT/RTT-l. The 16 gender- and age-matched normal controls (NC) were selected from our in-house database composed of electronic medical records from healthy participants without neurological disorders, neuropsychological disorders or epilepsy (Levman et al., 2017). Both datasets (RTT/RTT-l and NC) were comprised of examination acquired at BCH on the same suite of MRI scanners. The quality of the outputs of the CIVET pipeline (shapes of the brain mask, linear/non-linear registration to the template, tissue classification, and brain segmentation) were manually inspected for quality. This resulted in 8 volumetric structural brain MR images from 7 RTT/RTT-l patients with MECP2 mutations.

2.2. Structural MRI acquisition and processing

Three-dimensional (3-D) T1-weighted MPRAGE images (TR 2000–2500 ms; TE 1.7–2.5 ms, voxel size 0.85–1 × 0.85–1 × 1 mm, matrix 256 × 256) were obtained from all participants included in this study with clinical 3T MRI scanners (MAGNETOM Skyra, Siemens Medical Systems, Erlangen, Germany). DICOM files were collected through the Children’s Research and Integration System (Pienaar et al., 2015), and analyzed with CIVET version 2.1.0 pipeline (Zijdenbos et al., 2003) with MATLAB R2016a (MathWorks, Natick, MA). The quality of the outputs of the CIVET pipeline (shapes of the brain mask, linear/non-linear registration to the template, tissue classification, and brain segmentation) were manually inspected for quality. This resulted in 8 volumetric structural brain MR images from 7 RTT/RTT-l patients with MECP2 mutations.

2.3. Statistical analyses

Each brain structural measurement in RTT/RTT-l and NC participants were evaluated through Levene’s test for equality of variances and two-tailed unpaired t-test for equality of means. According to the false discovery rate correction for multiple comparisons by the Benjamini-Hochberg procedure (Benjamini et al., 2001; Reiner et al., 2003), Benjamini-Hochberg critical values (α = .05, q = .25) were determined for 57 and 40 repeating t-tests in surface- and voxel-based measurements, respectively. IBM SPSS Statistics version 19 (IBM Corp. Armonk, NY) was used for the statistical analysis. Regional cortical thickness was statistically analyzed and visualized as t-statistic maps, random field theory (RFT) maps, and false discovery rate (FDR) maps using the SurfStat toolbox (http://www.math.mcgill.ca/keith/surfstat/) with MATLAB R2016a (MathWorks, Natick, MA).

3. Results

3.1. Participants’ background

Clinical information for the 7 RTT/RTT-l participants are shown in Table 1. All participants were females, and born at term gestation. Age at MRI scans were not statistically significantly different (T (22) = -.011, P = .991) between RTT/RTT-l (N = 8) and NC (N = 16) based on Student’s t-test (the mean [standard deviation] were 5.2 [3.3] and 5.2 [3.2] years old in RTT/RTT-l and NC participants, respectively). Qualitative analyses of brain MRI showed no abnormal parenchymal findings in both RTT/RTT-l and NC participants, except for high signal intensity in T2-weighted images in the right cerebellar hemisphere in case 7.

3.2. Voxel-based volumetric analysis

Global and regional volumes in the cerebrum showed no statistically
significant difference between RTT/RTT-l and NC participants (Tables 2 and 3), while bilateral cerebellar hemispheres demonstrated statistically significantly decreased volumes in RTT/RTT-l compared to those in NC (the rate of RTT/RTT-l to NT = 0.85, 0.86, and 0.86, absolute Cohen’s d = 1.3, 1.22, and 1.27, and p = .0064, .010, and .008 in left, right, and total cerebellum, respectively). Scatter plots (volume vs. age) showed that the decrease in cerebellar volume was not age-dependent but rather case-dependent (Fig. 2). Genotype-phenotype correlation (correlation between mutation diversities and total cerebellar volumes) was not seen between RTT/RTT-l patients with intact or aberrant cerebellar volume.

3.3. Surface-based cortical analysis

The surface-based analyses showed that in the cerebrum, the surface area, thickness, volume, and GI were not statistically significantly different between RTT/RTT-l and NC participants (Tables 4 and 5). Fig. 1 shows a cortical thickness map superimposed on a 3-D template brain surface. The t-tests showed increased thickness in the right insula, and decreased thickness in the left precentral gyrus and left cuneus in RTT/RTT-l (Fig. 1). After the correction for multiple comparisons with RFT (p < .02) and FDR (p < .05), there was no region that showed statistically significantly different thickness in the cortex between RTT/RTT-l and NC.

4. Discussion

We analyzed surface- and voxel-based measurements in structural brain MRI of patients with RTT. The global cortical gyri, thickness, and volume (Tables 2 and 3), as well as regional cortical thickness (Fig. 1) in surface-based analysis, and the regional volumes of the cerebrum (Table 4) in voxel-based analysis showed no statistically significant difference between RTT/RTT-l and NC participants. The volumes of bilateral cerebellar hemispheres (Table 3) were significantly
Although acquired microcephaly is an essential clinical manifestation in RTT, only some studies have reported results of quantitative analyses of structural brain MRI in RTT (Reiss et al., 1993; Casanova et al., 1991; Murakami et al., 1992; Subramaniam et al., 1997; Carter et al., 2008). Previous studies reported decreased volumes in the cerebrum (Reiss et al., 1993; Casanova et al., 1991; Murakami et al., 1992; Subramaniam et al., 1997; Carter et al., 2008), basal ganglia (Reiss et al., 1993; Casanova et al., 1991; Murakami et al., 1992), cerebellum (Casanova et al., 1991; Murakami et al., 1992), corpus callosum (Murakami et al., 1992), and brainstem (Reiss et al., 1993; Murakami et al., 1992) in RTT compared to those in NC. The volume reduction of the cerebrum and the cerebellum have been confirmed in brain MRI studies with a mecp2 hetero- or homozygous-knockout mouse model (Ward et al., 2008; Allemang-Grand et al., 2017; Saywell et al., 2006).

However, in our study, a statistically significant difference between RTT/RTT-l and NC was observed only in the cerebellar volume. Given that the RTT/RTT-l patients in our study were younger than the prior studies (mean age: 5.2 years old, compared to 5.3–12 years old in the past studies) (Reiss et al., 1993; Casanova et al., 1991; Murakami et al., 1992; Subramaniam et al., 1997; Carter et al., 2008), it is possible to interpret our results to suggest that the cerebellar volume loss precedes atrophy of other brain regions, which potentially can contribute to an early diagnosis of RTT/RTT-l.

Abbreviation: RTT, Rett syndrome; RTT-l, Rett-like syndrome; NC, normal controls; N.A., not acquired.

Fig. 1. Visualized cortical thickness with t statistics map showing thicker lesions in Rett and Rett-like syndrome (RTT/RTT-l, N = 8) than normal controls (NC, N = 16). In the color scale, blue and red indicate less and greater in mean cortical thickness in RTT/RTT-l, respectively, compared to NC (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article).

Fig. 2. Scatter plots (age vs. volume) of total cerebellar volume. Closed circles and open circles indicate Rett and Rett-like syndrome (RTT/RTT-l, N = 8) and normal controls (NC, N = 16), respectively.

Although acquired microcephaly is an essential clinical manifestation in RTT, decreased in RTT/RTT-l compared to those in NC.
It is reasonable for the loss of cerebellar volumes to be associated with RTT, because RTT patients and mouse models present cerebellar symptoms; e.g. truncal ataxia (Diagnostic criteria for Rett syndrome, 1988; Temudo et al., 2008) and tremor (Temudo et al., 2008) in RTT patients and, tremor (Chen et al., 2001; Guy et al., 2001) and ataxic gait (Gadalla et al., 2014) in mepc2-deficient mice. Postmortem examinations of the cerebellum of five RTT females ranging in age from 7 to 30 years revealed a loss of Purkinje cells, atrophy and gliosis (Oldfors et al., 1990). In heterozygous mepc2-deficient mice, the cell bodies of cerebellar granule neurons are smaller and more densely packed than those in the wild type (Chen et al., 2001).

The MECP2 protein, encoded by MECP2, is a chromatin-associated protein, which binds to methylated DNA and modiﬁes transcription (Lyst and Bird, 2015). In humans, MECP2 expression increases after birth and maintains high expression levels in mature neurons and glial cells of the cerebrum and in molecular layers of the cerebellum (Armstrong et al., 1995). In the cerebrum, MECP2 maintains normal function of mature neurons (Lyst and Bird, 2015; Cheval et al., 2012; McGraw et al., 2011; Nguyen et al., 2012) and morphology of neural dendrites (Ballas et al., 2009), but does not regulate neuronal morphology (Lyst and Bird, 2015). Given that the cerebellum develops until the first postnatal years in humans, unlike the cerebrum (Ten Donkelaar and Lammens, 2009), MECP2 expression in postnatal periods likely contributes to cerebellar development (Armstrong et al., 1995; Mullaney et al., 2004; Liu et al., 2017) along with a maintenance role in the cerebrum. The literature and our current findings that regional decreased volume was observed only in the cerebellum in patients with RTT/RTT-I together suggest that early brain abnormalities likely caused by MECP2 in patients with RTT/RTT-I can be detectable as decreased volumes of the cerebellar hemispheres with structural MRI.

5. Conclusion

We analyzed structural brain MRI examinations of children with RTT/RTT-I by surface- and voxel-based measurements, and found statistically significantly decreased volumes of the cerebellum in RTT/RTT-I compared to those in normal controls. In contrast, cerebral cortical area, thickness, volumes, and gyriﬁcation, as well as subcortical gray matter volumes were not statistically signiﬁcant between the two groups. The decreased cerebellar volume may be helpful for understanding the etiology of RTT/RTT-I.

Author contributions

T.S. was responsible for study design. T.S. and J.L. analyzed data, and T.S., J.L., and E.T. wrote/edit the manuscript.

Conflict of interest

T.S., J. L., and E. T. declare relevant no conﬂicts of interest.

Study funding

This research project was supported by NIHR01HD078561, R21MH118739, and R03NS101372 to E.T.

Ethical approval

All procedures performed in studies involving human participants were in accordance with the ethical standards of the institutional and/or national research committee and with the 1964 Helsinki declaration and its later amendments or comparable ethical standards. For this type of study formal consent is not required.
